1. Executive Summary

This project presents a comprehensive design, implementation, and evaluation of a simple calculator that uses a stack-based evaluator for arithmetic expressions. The calculator follows a classical two-phase approach: conversion of infix expressions to postfix using Dijkstra's Shunting Yard algorithm, followed by evaluation of the resulting postfix (Reverse Polish Notation) expression using a value stack. The methodology exploits the Last-In-First-Out (LIFO) property of stacks to handle operator precedence, associativity, and parentheses deterministically and in linear time.

The report surveys theoretical underpinnings of stacks, formalizes infix/prefix/postfix notations, and articulates algorithmic components including tokenization, precedence tables, associativity rules, and evaluation semantics. It then presents a complete implementation in both Python and Java, with detailed pseudocode, complexity analysis, and testing methodology. Real-world applications are examined in compilers, scientific calculators, spreadsheet engines, and mathematical software. The results demonstrate O(n) time and O(n) space complexity for both conversion and evaluation under typical assumptions, with robustness over a range of edge cases including unary operators, exponentiation, floating-point inputs, and error handling. The report concludes with a roadmap for advanced features such as variable binding, function calls, symbolic manipulation, and just-in-time parsing optimizations.

---

2. Introduction

The reliable evaluation of arithmetic expressions is fundamental to computer science, underpinning compiler front-ends, interpreters, calculators, and spreadsheet systems. A core challenge is the disambiguation of infix expressions with nested parentheses and multiple precedence levels. Stack-based evaluation provides a principled and efficient solution by separating parsing concerns from computation using disciplined data structures and well-specified algorithms.

2.1 Background and Context

Arithmetic expressions—comprising numbers, operators, and parentheses—are ubiquitous across programming languages and end-user tools. Historically, infix notation is human-friendly but ambiguous without explicit parsing rules. Reverse Polish Notation (postfix) resolves ambiguity by encoding evaluation order directly into the token sequence, eliminating the need for parentheses. Dijkstra's Shunting Yard algorithm translates infix into postfix by maintaining an operator stack, enabling single-pass conversion with linear complexity.

2.2 Problem Statement and Rationale

The problem addressed in this project is designing and implementing a robust, extensible simple calculator that:

- Converts infix expressions into postfix notation while respecting precedence and associativity.
- Evaluates postfix expressions over integers and floating-point numbers.
- Handles errors and edge cases such as mismatched parentheses, invalid tokens, divide-by-zero, and unary operators.

This approach is rational due to clarity, determinism, and efficiency. The separation of phases improves maintainability and enables independent testing of conversion and evaluation.

2.3 Scope and Delimitations

Scope:

- Arithmetic operators: addition (+), subtraction (-), multiplication (*), division (/), exponentiation (^).
- Parentheses: (and).

- Operands: integers and floating-point numbers.
- Unary minus (negation) support.
- Whitespace-tolerant tokenization.

Delimitations:

- No variable assignment or symbolic names (baseline version).
- No functions in the base implementation (e.g., sin, cos), though addressed in Future Scope.
- No big-integer arithmetic or arbitrary precision by default (language-dependent).

2.4 Overview of Structure

The report proceeds from foundational theory to implementation details and validation. Following the objectives and motivation, the theory section formalizes notations, parsing, precedence, and literature. Implementation covers design, architecture, and code in Python and Java. Applications and case studies establish relevance. Testing and results quantify performance and robustness. Future scope charts advanced features and research directions. References and GitHub documentation complete the package.

---

3. Objectives

3.1 Primary Objectives

- Design a stack-based evaluator that converts infix to postfix and evaluates postfix reliably.
- Provide correct, efficient implementations in Python and Java.
- Demonstrate linear-time performance with rigorous complexity analysis.

3.2 Secondary Objectives

- Build a modular architecture for extension to variables, functions, and additional operators.
- Establish comprehensive testing and QA practices.
- Document algorithms and provide pedagogical walkthroughs.

3.3 Measurable Outcomes and KPIs

- Functional correctness: ≥ 99% pass rate on a curated test suite of ≥ 200 cases.
- Performance: O(n) time and O(n) space on inputs up to 10^6 characters in streaming tests.
- Robustness: graceful error messages for ≥ 10 distinct error categories.
- Code quality: maintainability metrics (cyclomatic complexity ≤ 10 for core modules).
- Documentation completeness: full API docs and user guide.

---

4. Why I Chose This Topic

4.1 Personal Motivation

Stack-based evaluators elegantly combine theory and practice. Implementing them sharpens understanding of data structures, grammars, and algorithmic design, while producing tangible, user-facing functionality.

4.2 Relevance to Academic and Career Goals

Expression parsing is foundational for compiler design, language tooling, and data processing systems. Mastery of these concepts prepares for roles in software engineering, systems programming, and language development.

4.3 Significance for Computer Science

This topic is central to language processing, formal methods, and algorithm engineering. It demonstrates how abstract structures (stacks) solve real parsing constraints, bridging discrete math and systems implementation.

---

5. Theory of Stack-Based Expression Evaluation

5.1 Stack Data Structure Fundamentals

A stack is a LIFO structure supporting:

- push(x): insert at top
- pop(): remove and return top element
- peek(): observe top element without removal
- isEmpty(): test emptiness

Stack semantics align naturally with nested constructs and deferred operations. In expression evaluation, stacks hold operators (for precedence handling) and operands (for computation).

5.2 Infix, Prefix, and Postfix Notations

- Infix: A + B. Operator between operands; requires precedence/associativity to disambiguate.
- Postfix (RPN): A B +. Evaluation proceeds left-to-right with a value stack.
- Prefix: + A B. Evaluation proceeds right-to-left with a value stack.

Postfix eliminates parentheses by encoding order directly in token sequence.

5.3 Shunting Yard Algorithm by Dijkstra

Purpose: Convert infix to postfix deterministically.

Given token stream T = t1, t2, ..., tn:

- Output list O (initially empty)
- Operator stack S (initially empty)
- Precedence π(^) > π(*) = π(/) > π(+) = π(-)
- Associativity α(^) = right; α(*, /, +, -) = left

Algorithm (informal):

- If token is operand → append to O.
- If token is operator op1 → while S not empty and top op2 has higher precedence, or equal with left associativity, and top is not '(' → pop op2 to O; push op1 on S.
- If token is '(' → push to S.
- If token is ')' → pop to O until '(' is popped and discarded.
- After input → pop all remaining operators to O.

Time complexity: O(n). Space complexity: O(n).

5.4 Expression Parsing Theory

Arithmetic expressions form a subset of context-free grammars. A canonical grammar:

E → E + T | E - T | T
T → T * F | T / F | F
F → P ^ F | P
P → (E) | num | -P

Left recursion is typically eliminated or handled by precedence climbing. The Shunting Yard simulates a precedence-aware parse by pushing operators until reductions are safe, akin to shift-reduce parsing.

5.5 Operator Precedence and Associativity

Define precedence levels:

- Level 3: ^ (right-associative)
- Level 2: * and / (left-associative)
- Level 1: + and - (left-associative)

Associativity resolves equal-precedence conflicts. For example, a - b - c parses as (a - b) - c due to left associativity; a ^ b ^ c parses as a ^ (b ^ c) due to right associativity.

5.6 Literature Review

- Dijkstra (1961): Introduced the Shunting Yard method for converting infix to RPN.
- Knuth, The Art of Computer Programming: Formalizes stacks and parsing strategies.
- Aho, Sethi, Ullman, Compilers (Dragon Book): Operator-precedence parsing and expression evaluation.
- Tarjan and others: Stack applications in algorithm design.
- Contemporary textbooks and peer-reviewed sources on parsing, data structures, and interpreters provide validation of linear-time behavior and practical engineering patterns.

---

6. Implementation

6.1 Methodology and Design

The system adopts a two-phase pipeline:

1. Tokenization and infix-to-postfix conversion via Shunting Yard.
2. Postfix evaluation using a value stack.

Separation ensures clearer invariants, simplified debugging, and modularity for future extensions (e.g., additional operators, functions).

Design principles:

- Deterministic single-pass algorithms per phase.
- Immutable tokens; explicit handling of unary minus.
- Clear error taxonomy with precise diagnostics.

6.2 Tools and Technologies

- Languages: Python 3.10+; Java 17+.
- Build/Test: Python venv/pytest; Maven/JUnit.
- Static analysis: flake8/black (Python), Checkstyle/SpotBugs (Java).

6.3 System Architecture

Layers:

- Lexer: converts string input to tokens (numbers, operators, parentheses).
- Parser: Shunting Yard producing postfix tokens.
- Evaluator: stack-based postfix interpreter.
- CLI/Service: user interaction, I/O, and error reporting.

Data flow: Input → Lexer → Parser → Postfix → Evaluator → Result.

6.4 Development Process

- Specification: Grammar, precedence, associativity, numeric types.
- Prototyping: Python first for rapid iteration; Java for static typing and performance.

- Testing: Unit tests for tokenization, parsing, evaluation; property-based tests for identities (e.g., a + 0 = a).
- Profiling and optimization: Microbenchmarks on large inputs.

6.5 Code Structure with Examples in Python and Java

Python package layout:

                else: raise ValueError(f"Unknown operator {op}")
        else:
            raise ValueError(f"Unexpected token {t}")
    if len(st) != 1:
```

```
        raise ValueError("Malformed expression")
    return st[0]
```

```
# calculator/cli.py
from .lexer import lex
from .parser import to_postfix
from .evaluator import eval_postfix

def evaluate_expression(expr: str) -> float:
    tokens = lex(expr)
    postfix = to_postfix(tokens)
    return eval_postfix(postfix)

if __name__ == "__main__":
    while True:
        try:
            s = input("calc> ")
            if s.strip().lower() in {"quit","exit"}: break
            print(evaluate_expression(s))
        except Exception as e:
            print(f"Error: {e}")
```

Step-by-step example:

- Input: 3 + 4 * 2 / (1 - 5) ^ 2 ^ 3
- Tokens: [3, +, 4, *, 2, /, (, 1, -, 5,), ^, 2, ^, 3]
- Postfix: 3 4 2 * 1 5 - 2 3 ^ ^ / +
- Evaluation: push 3; push 4; push 2; * → 8; push 1; push 5; - → -4; push 2; push 3; ^ → 8; ^ → (-4) ^ 8; / → 8 / ((-4)^8); + with 3.

}
```

6.6 Data Structures Used

- Operator stack (Deque/ArrayList): stores operators and parentheses during conversion.
- Output list: holds postfix tokens.
- Operand stack (Deque/ArrayList): holds numeric values during evaluation.
- Token representation: immutable records with kind and payload (number or operator).

---

7. Applications in Real Life

7.1 Compilers and Interpreters

Front-ends translate source code into intermediate forms. Expression parsing uses precedence-aware mechanisms akin to Shunting Yard or operator-precedence parsing. Postfix or abstract syntax trees (ASTs) enable machine-independent evaluation.

7.2 Scientific Calculators

Handheld and software calculators implement RPN or internally convert infix to postfix to simplify evaluation. Memory registers mirror stack frames for nested operations.

7.3 Spreadsheet Applications

Formulas like =SUM(A1:A5)*2+(B1^C1) are tokenized, parsed, and evaluated with precedence and function call semantics. Dependency graphs determine recomputation order, while expression evaluators compute cell values.

7.4 Programming Languages

Scripting engines (e.g., in browser devtools or DSL interpreters) implement expression evaluators that closely resemble the presented approach, extended with variables and functions.

7.5 Mathematical Software

CAS systems parse expressions, then either evaluate numerically or transform symbolically. Postfix or tree forms are used for subsequent transformations.

7.6 Case Studies

- Case Study 1: Implementing a safe calculator in an embedded system, focusing on deterministic memory usage.
- Case Study 2: Server-side expression evaluation for configurable business rules, emphasizing sandboxing and performance.
- Case Study 3: Educational IDE plugin demonstrating parsing steps to teach precedence and associativity.

---

8. Implementation and Testing

8.1 Testing Methodology

- Unit testing: individual modules (lexer, parser, evaluator) with boundary and randomized inputs.
- Integration testing: end-to-end evaluation from input string to result.
- Property-based testing: algebraic identities, commutativity (for +, *) and associativity where applicable.
- Negative testing: malformed inputs, invalid tokens, mismatched parentheses, divide-by-zero.

8.2 Test Cases and Validation

Representative cases:

- Basic: 2+2 → 4; 7-3*2 → 1.
- Parentheses: (1+2)*3 → 9.

- Exponentiation: $2^{3}2$ → 512 (right-associative).
- Unary: -3^{2} → $-(3^{2})$ = -9; (-3)^2 → 9.
- Floating-point: 3.5*2 → 7.0; 10/4 → 2.5.
- Errors: (1+2 → mismatched; 1/0 → division by zero; 2++3 → malformed.

Validation strategy:

- Cross-compare Python and Java outputs on the same corpus.
- Compare with a trusted RPN evaluator for randomized tests.

8.3 Debugging and Quality Assurance

- Logging parse stages: tokens, operator stack, output queue snapshots.
- Assertions in development builds for stack invariants.
- Static analysis and style enforcement.
- Code reviews and pair testing for ambiguity hotspots (unary/binary minus).

8.4 Edge Cases and Error Handling

- Unary operators at expression boundaries and after parentheses/operators.
- Deeply nested parentheses: ensure stack capacity and tail-behavior correctness.
- Large exponents and floating overflow/underflow: clamp or signal errors as configured.
- Locale-specific decimal separators: restrict to dot by default or add configurable tokenizer rules.

---

9. Results and Discussion

9.1 Findings and Performance Analysis

Empirical tests confirm linear scaling with input size. The conversion phase shows near-constant factor per token, while evaluation exhibits small overhead proportional to operator density. Memory usage scales linearly with the length of the longest operator/parenthesis nesting and token count.

9.2 Complexity Analysis

Let n be the number of tokens.

- Infix-to-postfix conversion:
  - Time: O(n) since each token is pushed and popped at most once.
  - Space: O(n) for output plus O(k) for operator stack, where k ≤ n.
- Postfix evaluation:
  - Time: O(n) with each operand pushed once and each operator popping/pushing a constant number of times.
  - Space: O(m) where m is max stack depth ≤ number of operands.

Overall pipeline: O(n) time, O(n) space.

9.3 Comparative Analysis

- Direct evaluation with precedence handling vs two-phase approach:
  - Direct evaluators are harder to reason about and test; two-phase method decouples concerns and eases optimization.
- Recursive descent vs Shunting Yard:
  - Recursive descent yields ASTs directly and is easier to extend with functions and variables.
  - Shunting Yard is simpler for pure arithmetic and produces a compact postfix representation without building trees.
- AST-based evaluation vs RPN evaluation:
  - AST affords optimizations (constant folding, algebraic rewrites).
  - RPN minimizes memory and avoids recursion.

9.4 Discussion of Limitations

- Lack of variables and functions limits expressiveness.
- Floating-point semantics may differ across platforms for edge values.
- Exponentiation associativity and precedence are language-specific and require careful documentation.
- Error messages can be improved with token indices and source ranges.

10. Future Scope

10.1 Technical Enhancements

- Variables and assignment: symbol table, lexical scoping.
- Functions: f(args...) with function table and arity check.
- Configurable operator sets and custom precedence tables.

10.2 Research Directions

- Expression JIT using bytecode or stack-machine instructions.
- Formal verification of evaluator correctness using property testing and model checking.
- Streaming evaluation for very large inputs with limited memory.

10.3 Advanced Features

- AST construction with optimization passes: constant folding, common subexpression elimination.
- Mixed numeric types: integers, decimals with arbitrary precision.
- Error recovery strategies and partial evaluation for IDE feedback.

10.4 Long-Term Vision

A full-featured expression engine suitable for embedding in applications, capable of parsing, evaluating, and transforming expressions with extensible syntax, robust diagnostics, and performance competitive with production interpreters.

---

11. Conclusion

This project demonstrates that stack-based evaluation provides a principled, efficient, and maintainable approach to arithmetic expression processing. By separating infix-to-postfix conversion from evaluation, the system achieves deterministic linear-time behavior and precise control over precedence and associativity. Implementations in Python and Java validate the theory and show portability. Comprehensive testing confirms robustness across a wide range of cases, while the architecture positions the

project for future extensions such as variables, functions, and optimizations. The methodology and artifacts serve as a strong foundation for educational use and real-world embedding.

Appendix A: Pseudocode Reference

Infix-to-Postfix (Shunting Yard) pseudocode:

```
function to_postfix(tokens):
    output ← empty list
    stack  ← empty stack
    prev   ← null
    for each t in tokens:
        if t is number:
            output.append(t)
        else if t is operator op:
            if op = '-' and (prev = null or prev ∈ {operator, '('}):
                op ← '~'  // unary minus
            if op = '~':
                while top(stack) = '~': output.append(pop(stack))
                push(stack, '~')
            else:
```

```
                while stack not empty and top(stack) is operator topOp and (
                      prec(topOp) > prec(op) or
                      (prec(topOp) = prec(op) and assoc(op) = left)):
                    output.append(pop(stack))
                push(stack, op)
        else if t is '(':
            push(stack, '(')
        else if t is ')':
            while top(stack) ≠ '(':
                output.append(pop(stack))
            if stack empty: error "mismatched"
            pop(stack) // discard '('
        prev ← t
    while stack not empty:
        if top(stack) ∈ {'(', ')'}: error "mismatched"
        output.append(pop(stack))
    return output
```

Postfix Evaluation pseudocode:

```
function eval_postfix(postfix):
    st ← empty stack
    for each t in postfix:
        if t is number: push(st, t.value)
        else if t is operator op:
            if op = '~':
                a ← pop(st)
                push(st, -a)
            else:
                b ← pop(st); a ← pop(st)
                push(st, apply(op, a, b))
    if size(st) ≠ 1: error "malformed"
    return pop(st)
```

Appendix B: Mathematical Notation

- Let Σ be the token alphabet; T ⊆ Σ tokens.
- Precedence function π: Operators → ℕ with π(^)=3, π(*, /)=2, π(+, -)=1.
- Associativity α: Operators → {left, right}; α(^)=right; α(+, -, *, /)=left.

- For input sequence $x_1 \ldots x_n \in T^*$, output $\varphi(x_1 \ldots x_n)$ is a postfix sequence computed by Shunting Yard; evaluation V maps postfix to $\mathbb{R}$ via stack reduction.
